Running title: Traits drive photoperiod cues in budburst

Summary

As the timing of plant life cycle events—phenology—has shifted with climate change, there is growing interest to incorporate phenology within plant strategies has received growing interest as phenology has shifted with climate change. But integrating phenology into existing spectra (like the leaf economic spectrum and wood economic spectrum) that consider traits across species has been slow in part because of high trait variation within-species, which is especially high for phenology. Addressing this requires data on many traits across space and better estimates of phenology, which is less variable when determined through experiments that can be used to decompose its environmental drivers (such as chilling and forcing temperatures or photoperiod). Here, working across eight forest communities to collect *in situ* trait measurements from 1428 individuals of 47 species, we find phenology connects to four major plant functional traits (height, diameter, leaf mass area and nitrogen content) via responses to photoperiod, but not temperature. These results provide insight into the complexity of phenology-trait relationships in relation to cues, as well as novel support for the inclusion of phenology in studies of woody plant growth to accurately forecasts changes in species growth with climate change.

Introduction

Climate change is causing species phenologies—the timing of life history events—to shift, with widespread advances being observed across the tree of life (Parmesan and Yohe, 2003; Hoegh-Guldberg et al., 2018). This common phenological fingerprint, however, averages over high variability across species (Thackeray et al., 2016; Cohen et al., 2018; Kharouba et al., 2018), posing a challenge to accurate forecasts.

In plants, species variation can be explained, in part, by differences in growth strategies, which are generally inferred from traits (Violle et al., 2007). Decades of research on plant traits have worked to build predictive models of species responses to their environment (Green et al., 2022), which could explain species-level variability in phenological responses. Phenology, however, has generally been excluded from plant trait research due to its high inter- and intra-specific variability, making it difficult to leverage existing frameworks to explain phenological variation and predict future changes. Previous studies have found high variation in phenology in observational studies—even for the same species when observed over different years or sites (Primack et al., 2009; Chuine et al., 2010), but variation is usually much smaller when calculated from controlled experiments, which suggest that phenological variation can be consistently decomposed into its environmental cues (e.g., temperature and photoperiod; Chuine and Cour, 1999; Harrington and Gould, 2015; Flynn and Wolkovich, 2018).

Correlations between plant traits, growth strategies, and responses to environments have been synthesized into several global frameworks, including the leaf economic spectrum (Wright et al., 2004) and wood economic spectrum (Chave et al., 2009). These frameworks have identified key traits that exhibit distinct gradients, ranging from acquisitive strategies—fast growing plants that produce cheaper tissue—to conservative strategies—with plants that invest in long-lived tissue but slower growth rates (Wright et al., 2004; Díaz et al., 2016). In temperate systems, changes in temperature and frost risk in spring can produce gradients in abiotic stress, including frost risk, soil nutrients, and light availability (Sakai and Larcher, 1987; Gotelli and Graves, 1996; Augspurger, 2009), in addition to differences in biotic interactions from herbivory or competition later in the season (Lopez et al., 2008; Wolkovich and Ettinger, 2014). Species that vary in their timing of leafout, should therefore exhibit traits and growth strategies that allow them to tolerate or avoid these abiotic and biotic factors. Leveraging insights from predictive models of phenology with these well established trait frameworks could begin to disentangle the environmental cues that shape phenology from those shaped by other trait differences in plant growth strategies.

To determine whether phenology fits within major functional trait frameworks requires working across within- and between-species variation. Phenological variation is generally observed in natural conditions where the environmental cues that trigger many phenological events—primarily temperature and photoperiod (Chuine, 2000; Körner and Basler, 2010)—vary across space and time. But experiments that control for this variation generally find smaller effects across space (Basler and Körner, 2014; Vitasse et al., 2009). Within-species variation also occurs across other plant traits (e.g., leaf and wood structure traits), including across latitudinal (Wiemann and Bruce, 2002) and other environmental gradients (Pollock et al., 2012), though generally to a smaller scale compared to phenology. To better understand how phenology and other traits correlate across species will require methods that incorporate spatial variation within species.

Here, we tested whether phenological variation was aligned with existing trait frameworks using data on spring budburst paired and a suite of traits that capture acquisitive to conservative growth strategies. We decompose the high phenological variation in budburst date by using experiments to estimate three major phenological cues for woody plant budburst: chilling (cool winter temperatures), forcing (warm spring temperatures), and photoperiod. We predict that early spring species will budburst before canopy closure, exhibited as smaller responses to temperature and photoperiod. These species should have traits associated with acquisitive growth, particularly shorter heights, smaller trunk or stem diameters, with lower investment in wood structure and leaf tissue, resulting in low wood specific density, diffuse-porous wood anatomy, and low leaf mass area, but high leaf nitrogen content for a greater photosynthetic potential. In contrast, we predict species with later budburst to predominately include canopy species that express more conservative growth strategies and require more chilling, warmer forcing, and longer photoperiods. These species should incur greater investments in long-lived tissue, with ring-porous wood anatomy, taller heights and greater diameter, denser wood and high leaf mass area, but low leaf nitrogen content. We then used a joint-modeling approach to estimate

the relationships between these plant traits and phenological responses to cues, while partitioning the variance from species- and population-level differences.

Materials and Methods

Field sampling

We combined *in situ* trait data with budburst data from two growth chamber cutting experiments conducted across eastern and western temperate deciduous forests in North America. We collected both suites of data from populations that span a latitudinal gradient of 4-6° for the eastern and western communities respectively. We took trait measurements from across eight populations, of which there were four eastern populations—Harvard Forest, Massachusetts, USA (42.55°N, 72.20°W), White Mountains, New Hampshire, USA (44.11°N, 52.14°W), Second College Grant, New Hampshire, USA (44.79°N, 50.66°W), and St. Hippolyte, Quebec, Canada (45.98°N, 74.01°W), and four western population—E.C. Manning Park (49.06°N, 120.78°W), Sun Peaks (50.88°N, 119.89°W), Alex Fraser Research Forest (52.14°N, 122.14°W), and Smithers (54.78°N, 127.17°W), British Columbia (BC), Canada (Fig. 1). For the two growth chamber studies on budburst phenology, we collected cuttings from the most southern and northern populations in each transect ($n_{pop}=4$).

Functional traits

We measured all traits in the summer prior to each growth chamber study (eastern transect: 8-25 June 2015, western transect: 29 May to 30 July 2019), following full leafout but before budset. At each population and for each species, we measured a total of five traits from 1-10 healthy adult individuals: height, diameter of the main trunk or stem (hereafter referred to as diameter), wood specific density, leaf mass area, and the percent leaf nitrogen content. We also obtained xylem structure data from the WSL xylem database (Schweingruber and Landolt, 2010) for 72.3% of our species.

We measured traits in accordance to the methods discussed by Pérez-Harguindeguy et al. (2013). We calculated tree height using trigonometric methods and used a base height of 1.37 m to measure diameter (Magarik et al., 2020). For shrub heights, we measured the distance from the ground to the height of the top foliage and measured stem diameters at approximately 1 cm above ground-level. All stem and leaf samples were kept cool during transport and measurements of leaf area and stem volume taken within 3 and 12 hours of sample collection respectively. To measure wood specific density, we collected a 10 cm sample of branch wood, taken close to the base of the branch at the stem and calculated stem volume using the water displacement method. For our leaf traits, we haphazardly selected and sampled five, fully expanded, and hardened leaves, with no to minimal herbivore damage. We took a high resolution scan of each leaf using a flatbed scanner and estimated leaf area using the ImageJ software (version 2.0.0).

Growth chamber study

For our growth chamber studies, we collected branch cuttings from our highest and lowest latitude populations in each transect, with sampling in our eastern study occurring from 20-28 January 2015 and sampling for our western study from 19-28 October 2019. **In using cuttings from dormant branches, we are able to experimentally manipulate environmental cues while still approximating whole plant responses in budburst (Vitasse and Basler, 2014).** In both studies, we included a total of eight distinct treatments consisting of two levels of chilling, forcing, and photoperiods (Fig. 1). We recorded budburst stages of each sample every 1-3 days for up to four months, defining the day of budburst as the day of budbreak or shoot elongation (denoted as code 07 by Finn et al. (2007)). For a more detailed discussion of study sample collection and methods see Flynn and Wolkovich (2018) for details on our

136 eastern study and Loughnan and Wolkovich (in prep) for details on our western study.

137

138 Statistical Analysis

139 Our analysis combined our *in situ* trait data with budburst data from the controlled environment. For
 140 each trait, we developed a joint Bayesian model, in which the relationship between traits and cues
 141 is used to estimate budburst. This statistical approach improves upon previous analyses of multiple
 142 traits, as it allows us to carry through uncertainty between trait and phenology data—and better
 143 partitions the drivers of variation in species phenologies

144

145 Our joint model consists of two parts. The first is a hierarchical linear model, which partitions the vari-
 146 ation of individual observations (i) of a given trait value (Y_{trait}) to account for the effects of species
 147 (j), population-level differences arising from transects, latitude, as well as the interaction between
 148 transects and latitude ($\text{transect} \cdot \text{latitude}$), and finally, residual variation or ‘measurement error’ (σ_m^2).
 149

$$Y_{\text{trait}_{i,j}} \sim \text{Normal}(\mu_{i,j}, \sigma_m^2) \quad (1)$$

$$\mu_{i,j} = \alpha_{\text{grand trait}} + \alpha_{\text{trait}_j} + \beta_{\text{transect}} \times \text{transect} + \quad (2)$$

$$\beta_{\text{latitude}} \times \text{latitude} + \beta_{\text{transect} \cdot \text{latitude}} \times (\text{transect} \cdot \text{latitude}) \quad (3)$$

$$(4)$$

150

$$\alpha_{\text{trait}} \begin{bmatrix} \alpha_{\text{trait}_1} \\ \alpha_{\text{trait}_2} \\ \dots \\ \alpha_{\text{trait}_n} \end{bmatrix} \text{ such that } \alpha_{\text{trait}} \sim \text{Normal}(0, \sigma_{\text{trait}}^2) \quad (5)$$

$$(6)$$

151 We include transect as a dummy variable (0/1) and latitude as a continuous variable in our model.
 152 We modeled traits using their original units, with the exception of leaf mass area which was rescaled
 153 by 100 and wood specific density which was rescaled by 10 for numeric stability in the model. Our
 154 model also includes partial pooling for species—which controls for variation in the number of trait
 155 estimates per species and trait variability—using these species-level estimates as predictors for each
 156 cue ($\beta_{\text{chilling},j}$, $\beta_{\text{forcing},j}$, $\beta_{\text{photoperiod},j}$).
 157

$$\beta_{\text{chilling}_j} = \alpha_{\text{chilling},j} + \beta_{\text{trait.chilling}} \times \alpha_{\text{trait},j} \quad (7)$$

$$\beta_{\text{forcing}_j} = \alpha_{\text{forcing},j} + \beta_{\text{trait.forcing}} \times \alpha_{\text{trait},j}$$

$$\beta_{\text{photoperiod}_j} = \alpha_{\text{photoperiod},j} + \beta_{\text{trait.photoperiod}} \times \alpha_{\text{trait},j}$$

158 In addition to the species-level estimates, the second part of our model estimates the overall effect of
 159 each trait on each cue ($\beta_{\text{trait.chilling}}$, $\beta_{\text{trait.forcing}}$, $\beta_{\text{trait.photoperiod}}$). From this we can estimate how well
 160 traits explain species-level differences—by estimating the the species-level cue variation not explained
 161 by traits ($\alpha_{\text{chilling},j}$, $\alpha_{\text{forcing},j}$, $\alpha_{\text{photoperiod},j}$) and individual species responses to cues (*chilling*, *forcing*,
 162 *photoperiod*, respectively). Finally, our model estimates the residual budburst variation across species
 163 ($Y_{\text{pheno},j}$), observations (σ_d^2), as well as the variation in cues not attributed to the trait (using partial
 164 pooling).

$$Y_{\text{pheno}_{i,j}} \sim \mathcal{N}(\mu_{i,j}, \sigma_d^2) \quad (8)$$

165 with

$$\mu_{i,j} = \alpha_{\text{pheno}_j} + \beta_{\text{chilling}_j} \cdot \text{chilling} + \beta_{\text{forcing}_j} \cdot \text{forcing} + \beta_{\text{photoperiod}_j} \cdot \text{photoperiod} \quad (9)$$

166 where α_{pheno_j} , $\alpha_{\text{chilling}_j}$, $\alpha_{\text{forcing}_j}$, and $\alpha_{\text{photoperiod}_j}$ are elements of the normal random vectors:

$$\boldsymbol{\alpha}_{\text{pheno}} = \begin{bmatrix} \alpha_{\text{pheno}_1} \\ \alpha_{\text{pheno}_2} \\ \dots \\ \alpha_{\text{pheno}_n} \end{bmatrix} \text{ such that } \boldsymbol{\alpha}_{\text{pheno}} \sim \text{Normal}(\mu_{\text{pheno}}, \sigma_{\text{pheno}}^2) \quad (10)$$

$$\boldsymbol{\alpha}_{\text{chilling}} = \begin{bmatrix} \alpha_{\text{chilling}_1} \\ \alpha_{\text{chilling}_2} \\ \dots \\ \alpha_{\text{chilling}_n} \end{bmatrix} \text{ such that } \boldsymbol{\alpha}_{\text{chilling}} \sim \text{Normal}(\mu_{\text{chilling}}, \sigma_{\text{chilling}}^2) \quad (11)$$

$$\boldsymbol{\alpha}_{\text{forcing}} = \begin{bmatrix} \alpha_{\text{forcing}_1} \\ \alpha_{\text{forcing}_2} \\ \dots \\ \alpha_{\text{forcing}_n} \end{bmatrix} \text{ such that } \boldsymbol{\alpha}_{\text{forcing}} \sim \text{Normal}(\mu_{\text{forcing}}, \sigma_{\text{forcing}}^2) \quad (12)$$

$$\boldsymbol{\alpha}_{\text{photoperiod}} = \begin{bmatrix} \alpha_{\text{photoperiod}_1} \\ \alpha_{\text{photoperiod}_2} \\ \dots \\ \alpha_{\text{photoperiod}_n} \end{bmatrix} \text{ such that } \boldsymbol{\alpha}_{\text{photoperiod}} \sim \text{Normal}(\mu_{\text{photoperiod}}, \sigma_{\text{photoperiod}}^2) \quad (13)$$

(14)

167 We modeled each trait individually, with the exception of ring-porosity, which we compared across
 168 species using the posterior estimates of our wood stem density model, allowing us to account for inher-
 169 ent differences in wood anatomy across species and growth form. We included all three cues (chilling,
 170 forcing, and photoperiod) as continuous variables in our model, as well as all two-way interactions
 171 between cues and between cues and sites. We converted chilling temperatures to total chill portions,
 172 including both the chilling experienced in the field prior to sampling and during the experiment. For
 173 this we used local weather station data and the chillR package (v. 0.73.1, Luedeling, 2020). To account
 174 for differences in thermoperiodicity between the two studies (Buonaiuto et al., 2023), we also converted
 175 forcing temperatures to mean daily temperatures for each treatment. Finally, we z -scored each cue
 176 and site using two standard deviations to allow direct comparisons between results across parameters
 177 (Gelman, 2008).

178
 179 For each model we used trait specific priors that were weakly informative. We validated our choice
 180 of priors using prior predictive checks and confirmed model stability under wider priors. All models
 181 were coded in the Stan programming language for Bayesian models using the rstan package (Stan
 182 Development Team, 2018) in R version 4.3.1 (R Development Core Team, 2017). All models met basic
 183 diagnostic checks, including no divergences, high effective sample sizes (n_{eff}) that exceeded 10% of
 184 the number of iterations, and \hat{R} values close to 1. We report our model estimates as the mean values
 185 with 90% uncertainty intervals (UI), interpreting parameter estimates with intervals that overlap to
 186 be statistically similar to each other and those that include zero to have small effects.

187

Results

Across our eight populations, we measured 47 species of which 28 were in our eastern transect and 22 in our western transect. These include species dominant in both the understory and canopy layer, with our eastern community consisting of 13 shrubs and 15 trees, our western community consisting of 18 shrubs and 4 trees, and three species that occurred in both transects. In total we measured traits of 1428 unique individuals between the two transects across our five *in situ* traits: height ($n = 1317$), diameter ($n = 1220$), wood stem density ($n = 1359$), leaf mass area ($n = 1345$), leaf nitrogen content ($n = 1351$). Across our two growth chamber studies, we made observations of 4211 samples, with our observations of budburst spanning 82 and 113 days for our eastern and western studies respectfully.

Most of our traits showed some variation by latitude within each transect, with a strong interactive effect between transect and latitude (Fig. 2). Leaf nitrogen content was the only trait to vary with latitude alone, with low latitude communities on both our eastern and western transects having greater values of leaf nitrogen content than communities at higher latitudes (-0.1 percent per degree latitude, UI: -0.2, 0.0, Table S6). The strongest negative interaction was observed for height, while the strongest positive interaction was observed for leaf mass area. Height and wood stem density both exhibited negative transect by latitude interactions (-0.2 m per degree latitude, UI: -0.4, 0.0 for our height model and -0.01 g/cm³ per degree latitude, UI: -0.02, 0.0 for our wood stem density model), with woody species in our eastern communities exhibiting greater heights and wood stem densities with increasing latitude, but decreasing values with latitude in our western communities (Fig. 2 a and c). In contrast, diameter and leaf mass area both exhibited positive transect by latitude interactions (0.5 cm per degree latitude, UI: 0.1, 0.9 for our diameter model and 0.005 g/cm² per degree latitude, UI: 0.004, 0.006 for our leaf mass area model), with plants at higher latitudes having increasing diameters in both our eastern and western communities but decreasing leaf mass areas in our eastern communities and increasing values in our western communities (Fig. 2 b and d). In addition to the differences we found across populations, we also observed considerable differences between individual species, which varied considerably and up to 7 fold for some traits (Fig. 3).

We found that three of our four traits had a strong relationship with photoperiod, but not always in the direction we predicted. Taller species with larger trunk diameters and leaves with high nitrogen content had larger responses with longer photoperiods (Fig. 3 c, i, o; Tables S2, S3, S6). But, contrary to our expectation, species with denser, high leaf mass area leaves had smaller photoperiod responses, allowing them to potentially budburst under shorter photoperiods (Fig. 3f).

Temperature cues ($\beta_{\text{trait.chilling}}$ and $\beta_{\text{trait.forcing}}$) exhibited no relationships with individual traits, but by accounting for the effects of leaf or wood traits, we found the importance of our three cues on budburst to vary by trait. Of the three cues, chilling (β_{chilling}) was the strongest in our models of height (-13.4 days per standardized chill portions, UI: -17.2, -9.9), diameter (-12.5 days per standardized chill portions, UI: -16.2, -8.6), wood stem density (-20.9 days per standardized chill portions, UI: -33.2, -9.8), and leaf nitrogen content (-35.1 days per standardized chill portions, UI: -68.1, -4.1), with more chilling advancing budburst. Our model of leaf mass area, however, estimated photoperiod as the strongest cue ($\beta_{\text{photoperiod}}$, -14.0 days per standardized photoperiod, UI: -23.1, -3.5). After accounting for the effects of traits, only our height and diameter model found all three environmental cues to drive budburst timing (Tables S2, S3). Our models of wood stem density and leaf nitrogen content in turn found temperature cues alone to shape budburst (Tables S4, S6), while our model of leaf mass area found a large response to only photoperiod (Table S5).

In synthesizing the effects of multiple traits across species, our results can be used to make generalizations across ecologically important groups of species. But only some of our models estimated clear gradients in species timing between trees and shrubs. In particular, we found height to have large correlations between budburst timing and trait values, with earlier estimates of budburst for shrubs

(with a mean day of budburst of 10)—especially under greater cues—and later budburst estimates for trees (with a mean day of budburst of 17.3, Fig. S1). Diameter at breast height showed similar trends as estimates from our height model (results not shown). But this was not the case for our two leaf traits. Leaf nitrogen content, for example, showed no distinct separation between shrub and tree functional groups (Fig. S1).

244

245 Discussion

246 Using our joint modeling approach, we estimated how leaf and wood traits interact with temperature and photoperiod cues to shape species budburst. We found that photoperiod—often the weakest cue of budburst (Laube et al., 2014; Zohner et al., 2016; Flynn and Wolkovich, 2018)—was the most important cue in trait-phenology relationships. In general, we also found trait patterns varied between 249 our eastern and western transects and with latitude. These spatial differences in trait variation may be due to differences in the community assemblages, as our western community is more shrub dominated, with shorter plants with less dense branch wood. This more acquisitive growth strategy suggests these species are more likely to utilize resources early in the season prior to canopy closure. **Collectively our results provide new insights into the complex tradeoffs between cues and traits and how they differ across large spatial scales.**

256

257 Cues and functional traits

258 We found only partial support for our prediction that species with acquisitive traits—particularly small trees with low wood density, low leaf mass area, and high leaf nitrogen content—would have early budburst via smaller temperature and photoperiod responses. We did find species with smaller heights and diameters to have smaller photoperiod responses. But contrary to our prediction, species with less dense leaves showed larger responses to photoperiod, while leaves with high nitrogen content had stronger photoperiod responses. None of our focal traits, however, showed a relationship with temperature (chilling or forcing), which may be due to selection on other physiological processes. Many of our traits are associated with one or more ecological function (Wright et al., 2004; Pérez-Harguindeguy et al., 2013; Reich, 2014). In particular, leaf mass area is known to correlate with traits like leaf lifespan or decomposition rates in addition to light capture (De La Riva et al., 2016). While our results highlight the ways in which phenology partially aligns with gradients found in established trait frameworks, they also offer new insight into potential tradeoffs in how varying physiological processes shape species growth strategies.

271

272 Decades of previous phenology research have found budburst timing to be primarily driven by temperature (chilling and forcing) and weakly by photoperiod (Chuine et al., 2010; Basler and Körner, 2014; Laube et al., 2014). But we found no other traits that correlate with responses to temperature, **suggesting other cues or biotic interactions may impact** leaf and structural traits in temperate forests. Leaf mass area also varies with soil moisture, with variation in leaf area allowing plants to reduce evaporation under dry conditions, and thus selecting for high trait values (De La Riva et al., 2016). Soil moisture shapes other phenological events in woody plants, including radial growth phenology and shoot elongation (Cabon et al., 2020; Peters et al., 2021). If selection by soil moisture is shaping phenological responses, it may be contributing to the unexpected trends we observed in leaf traits and the absence of relationships with temperature. **To fully understand how species growth strategies correlate with phenology may thus require additional environmental factors to be considered.**

283

284 The absence of trait-cue relationships between budburst and wood structure and wood stem density contrasts the findings of previous work linking these traits. Previous studies have found some evidence

285

that trees with diffuse-porous wood structure leafout earlier than species with ring-porous structures (Lechowicz, 1984; Panchen et al., 2014; Yin et al., 2016; Osada, 2017; Savage et al., 2022). But, using wood density as an alternative measure of wood structure (wood density positively correlates with xylem resistance to embolism, Hacke et al., 2001), we did not find clear association between our three phenological cues and xylem structure, despite our data also including similar temperate forest species. Most of the individuals we measured, however, did have a fairly narrow range of wood specific densities (varying from 0.2 to 0.6 g/cm³) relative to the variation in wood density observed in studies that include tropical species or span a more global distribution (Galvão et al., 2021; Savage et al., 2022; Mo et al., 2024). We did find some variation in wood density across our different sites and with latitude. The larger wood densities we observed at higher latitudes in our eastern transect could be caused by the differences in winter conditions experienced by canopy versus understory species. The canopy tree species that dominate our eastern communities may experience greater horizontal stress from wind and downward pressure from snow, explaining the greater wood densities they exhibit at higher latitudes (MacFarlane and Kane, 2017; MacFarlane, 2020), while species in the shrub dominated western communities experience greater protection from being in the understory.

In addition to our study providing insight into how trait-budburst relationships vary with latitude, our sites also span North America, encompassing a gradient of 55° in longitude. At this continental scale, our data spans a large portion of the temperate forest biome of North America, which may partially explain the lack of stronger correlations between phenology and traits. While both the leaf and wood economic spectra find large variation in traits across species, the foundational studies from which they arose all used large global datasets that include both temperate and tropical species (Wright et al., 2004; Díaz et al., 2016; Chave et al., 2009) and functional groups that span from trees to grasses (Wright et al., 2004). Previous research also suggests that global patterns in trait variation are often not found at smaller spatial scales (Wright and Sutton-Grier, 2012; Messier et al., 2017a,b). This suggests that comparing trait-phenology relationships at larger spatial scales or across more diverse pools of species would may better align with the patterns predicted by existing economic spectra. While our results explain trait correlations in temperate forests, they could potentially be extended to similar forest biomes Europe that experience comparable environmental conditions.

In comparing our results with a global meta-analysis of tree trait relationships with budburst cues (Loughnan et al., 2025), we found similar trait-cue relationships for height and leaf mass area. At both the global and continental scales, trees with taller heights leafed out with longer photoperiods. We also found species with high specific leaf area—which is the inverse of leaf mass area and thus equivalent to low values—exhibited large responses to photoperiod (Loughnan et al., 2025). The consistency of these results, despite the differences in the two spatial scales of these datasets, provides further support that alternate underlying mechanisms are shaping how woody species respond to photoperiod cues.

Functional traits predict climate change responses

Our results offer novel insights into how broader correlations between growth strategies and phenological cues can help predict responses in woody plant communities with climate change. As temperatures rise, particularly at higher latitudes (Hoegh-Guldberg et al., 2018), warmer winter and spring temperatures may select for earlier budburst in some species. But, since photoperiod will remain fixed, our observed relationships between photoperiod and other traits has the potential to limit species abilities to track temperatures. This could constrain the extent to which some species growth will advance with climate change. Our results suggest that these effects will likely be greater for taller species or canopy trees and species with relatively low leaf mass area. These constraints could have cascading effects on forest communities, as variable species responses to increasing temperatures further alter species growth strategies and their interactions with competitors or herbivores within their communities.

Our findings of correlations between phenology and other commonly measured traits highlight how accurate forecasts of future changes in phenology can benefit from accounting for the response of other traits to climate change. Across temperature and precipitation gradients, leaf size and shape also change, as species shift to conserve water and mitigate effects of transpiration under higher temperatures (De La Riva et al., 2016). These changes could impact species photosynthetic potential and ultimately ecosystem services, such as carbon sequestration. While phenological research has focused on forecasting responses to temperature, the correlation of other traits with photoperiod suggests it is also an important cue. By considering the tradeoffs and differences in cues that simultaneously shape plants growth strategies, we can more accurately forecast species phenology and community dynamics under future climates.

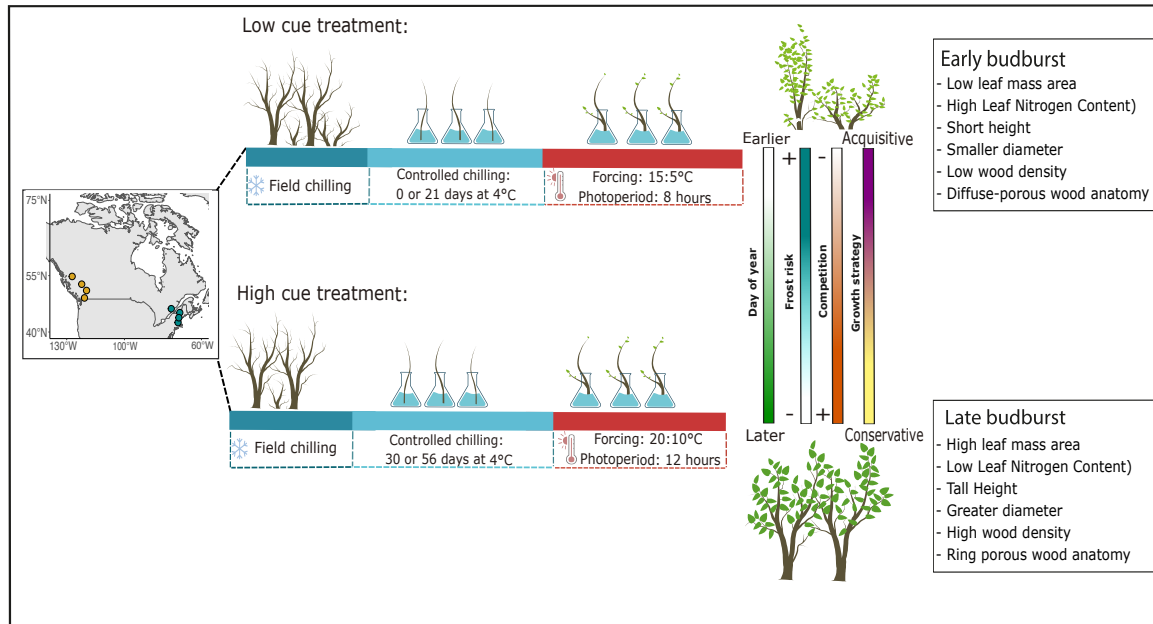

Figure 1: We collected trait data and branch cuttings from woody plants growing within eight sites, across two transects in eastern and western North America. Cuttings were used in two controlled environment studies in which we applied high and low chilling, forcing, and photoperiod treatments and recorded the day of budburst. Using our paired *in situ* trait and experimental budburst data, we tested whether earlier budbursting species exhibited traits associated with more acquisitive growth strategies and smaller responses to cues and later budbursting species a more conservative growth strategy and larger responses to cues.

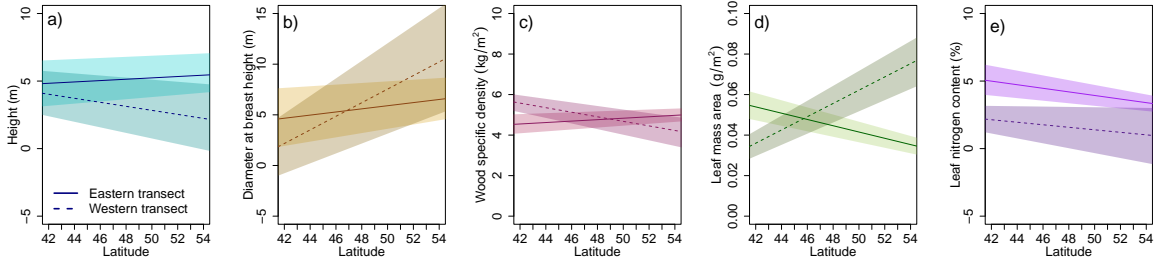

Figure 2: We found a. height, b. diameter, c. branch stem density, and d. leaf mass area to all experience a strong interaction between latitude and transect, e. while leaf nitrogen content showed a strong effect of latitude alone.

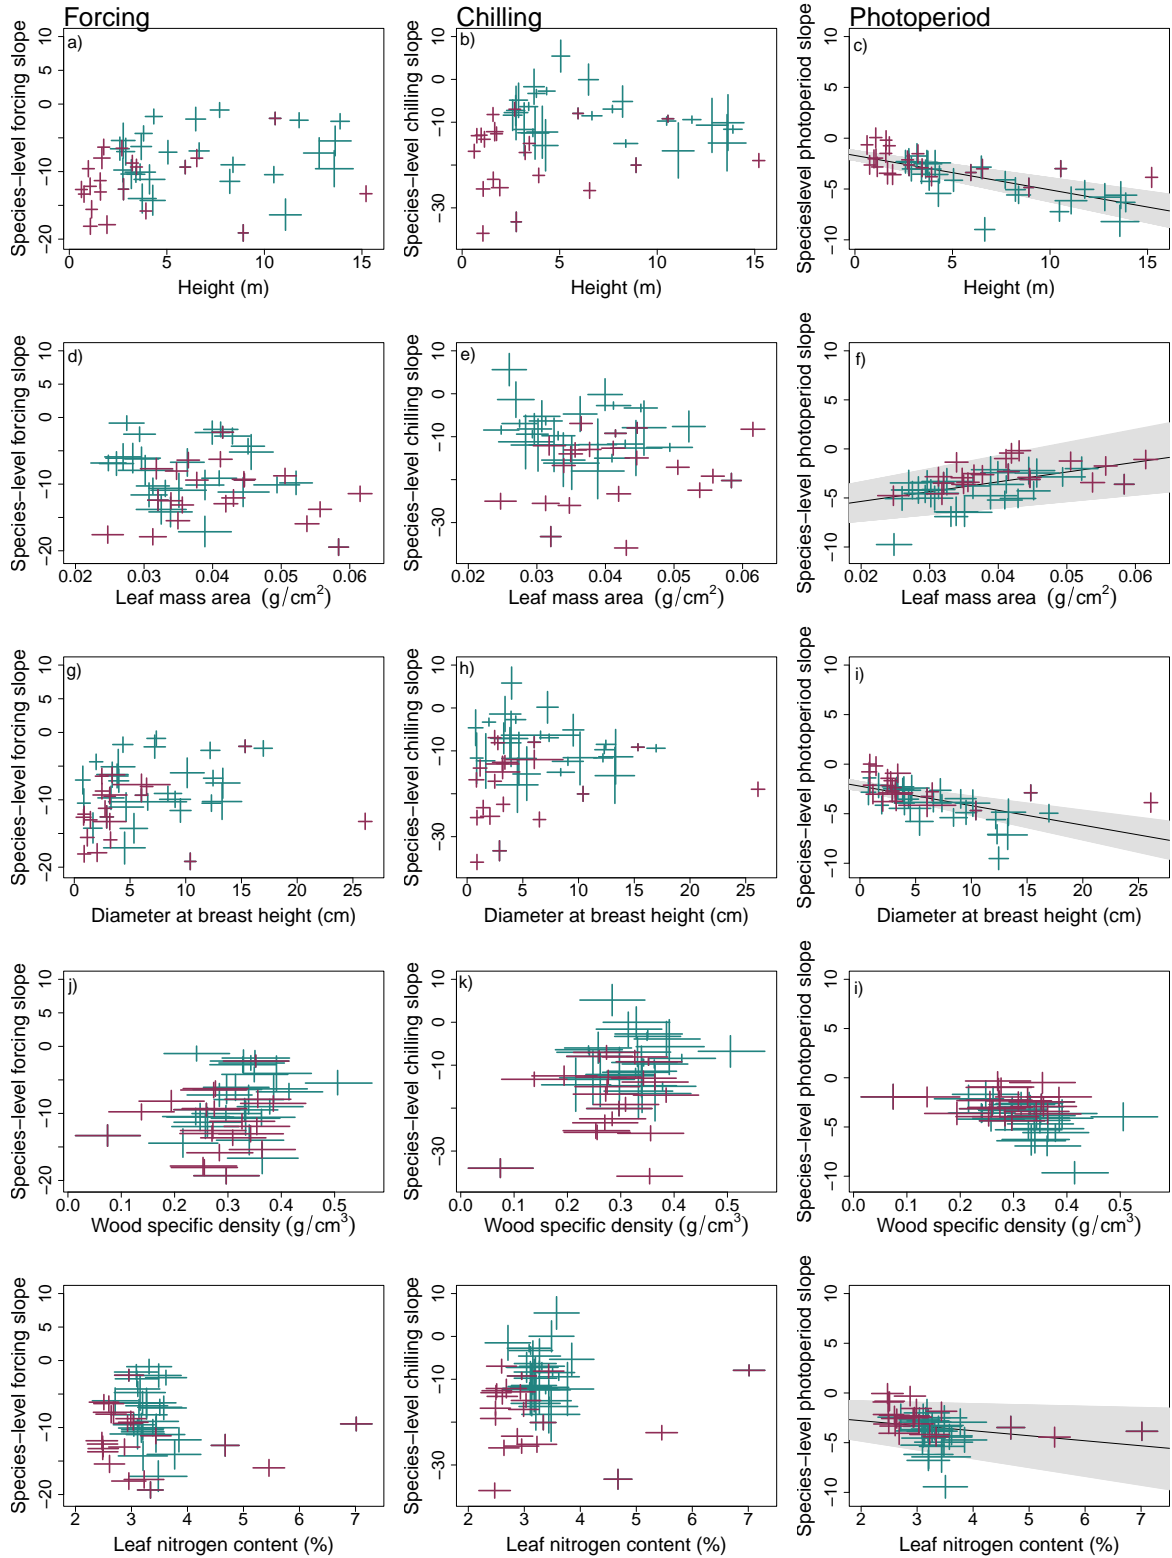

Figure 3: Relationships between species traits and cue responses showed considerable variation across a-c. height, d-f. leaf mass area, g-i. diameter, j-l. wood specific density, and m-o. the leaf nitrogen content. Point colours representing different species groups, with tree species shown in red and shrub species in blue. Crosses depict the 50% uncertainty interval of the model estimates of species trait values and estimated responses to cues. Grey bands depict large relationships between a trait and cue, representing the 90% uncertainty interval, and black lines the mean response.

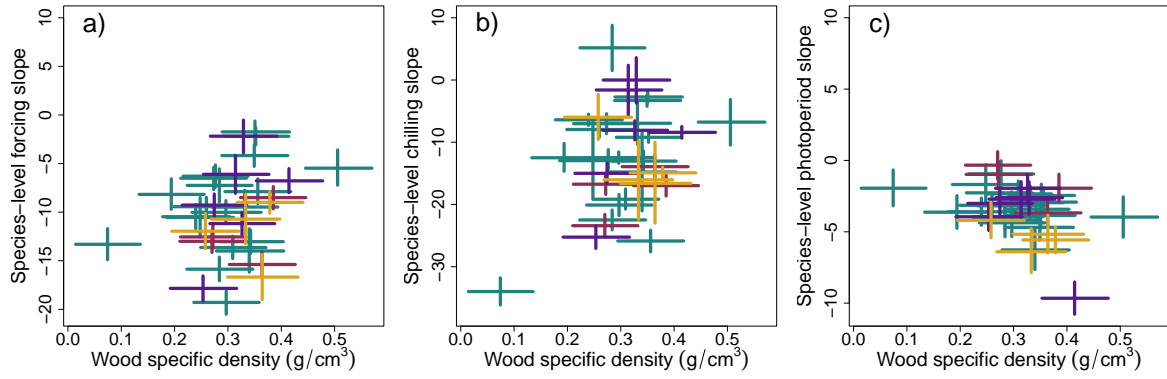

Figure 4: Despite previous studies finding relationships between leaf out timing and species wood xylem structures, we did not find clear differences in species-level estimates of cue responses with wood structure or relative to their wood specific densities. Each cross represents the 50% uncertainty interval of **a.** forcing, **b.** chilling, and **c.** photoperiod responses and wood specific density, with colors depicting different types of wood structure. The lowest wood specific density was estimated for *Sambucus racemosa* and the highest wood specific density for *Viburnum lantanoides*.
